Appendix A. Data Generation

A.1. *Simulation Scheme*

While observational data is frequently employed in training models for real-world applications, the data generating process of observational data often remains unknown, making computation for our target variable D unattainable. Consequently, the computer vision models developed in this study were trained using synthetic data, including 80,000 training images and 8,000 test images. This approach provided us with precise label annotations. Additionally, it ensured a large and diverse training dataset, as we had control over the data generating process, and the simulation of the training data was relatively cost-effective.

We have incorporated three types of residual departures of linear regression model in the training data, including non-linearity, heteroskedasticity and non-normality. All three departures can be summarized by the data generating process formulated as

Table A1. Factors used in the data generating process for synthetic data simulation. Factor j and a controls the non-linearity shape and the heteroskedasticity shape respectively. Factor b , σ_ε and n control the signal strength. Factor dist_ε , dist_{x_1} and dist_{x_2} specifies the distribution of ε , X_1 and X_2 respectively.

| Factor | Domain |
|---------------------------|---|
| j | $\{2, 3, \dots, 18\}$ |
| a | $[-1, 1]$ |
| b | $[0, 100]$ |
| β_1 | $\{0, 1\}$ |
| β_2 | $\{0, 1\}$ |
| dist_ε | $\{\text{discrete, uniform, normal, lognormal}\}$ |
| dist_{x_1} | $\{\text{discrete, uniform, normal, lognormal}\}$ |
| dist_{x_2} | $\{\text{discrete, uniform, normal, lognormal}\}$ |
| σ_ε | $[0.0625, 9]$ |
| σ_{X1} | $[0.3, 0.6]$ |
| σ_{X2} | $[0.3, 0.6]$ |
| n | $[50, 500]$ |

$$\mathbf{y} = \mathbf{1}_n + \mathbf{x}_1 + \beta_1 \mathbf{x}_2 + \beta_2 (\mathbf{z} + \beta_1 \mathbf{w}) + \mathbf{k} \odot \boldsymbol{\varepsilon}, \quad (\text{A1})$$

$$\mathbf{z} = \text{He}_j(g(\mathbf{x}_1, 2)), \quad (\text{A2})$$

$$\mathbf{w} = \text{He}_j(g(\mathbf{x}_2, 2)), \quad (\text{A3})$$

$$\mathbf{k} = [\mathbf{1}_n + b(2 - |a|)(\mathbf{x}_1 + \beta_1 \mathbf{x}_2 - a \mathbf{1}_n)^{\odot 2}]^{\odot 1/2}, \quad (\text{A4})$$

where \mathbf{y} , \mathbf{x}_1 , \mathbf{x}_2 , \mathbf{z} , \mathbf{w} , \mathbf{k} and $\boldsymbol{\varepsilon}$ are vectors of size n , $\mathbf{1}_n$ is a vector of ones of size n , \mathbf{x}_1 and \mathbf{x}_2 are two independent predictors, $\text{He}_j(\cdot)$ is the j th-order probabilist's Hermite polynomials (Hermite 1864), $(\cdot)^{\odot 2}$ and $(\cdot)^{\odot 1/2}$ are Hadamard square and square root, \odot is the Hadamard product, and $g(\mathbf{x}, k)$ is a scaling function to enforce the support of the random vector to be $[-k, k]^n$ defined as

$$g(\mathbf{x}, k) = 2k \cdot \frac{\mathbf{x} - x_{\min} \mathbf{1}_n}{x_{\max} - x_{\min}} - k \mathbf{1}_n, \text{ for } k > 0,$$

where $x_{\min} = \min_{i \in \{1, \dots, n\}} x_i$, $x_{\max} = \max_{i \in \{1, \dots, n\}} x_i$ and x_i is the i -th entry of \mathbf{x} .

The residuals and fitted values of the fitted model were obtained by regressing \mathbf{y}

on \mathbf{x}_1 . If $\beta_1 \neq 0$, \mathbf{x}_2 was also included in the design matrix. This data generation process was adapted from Li et al. (2024), where it was utilized to simulate residual plots exhibiting non-linearity and heteroskedasticity visual patterns for human subject experiments. A summary of the factors utilized in Equation A1 is provided in Table A1.

In Equation A1, \mathbf{z} and \mathbf{w} represent higher-order terms of \mathbf{x}_1 and \mathbf{x}_2 , respectively. If $\beta_2 \neq 0$, the regression model will encounter non-linearity issues. Parameter j serves as a shape parameter that controls the number of tuning points in the non-linear pattern. Typically, higher values of j lead to an increase in the number of tuning points, as illustrated in Figure A1.

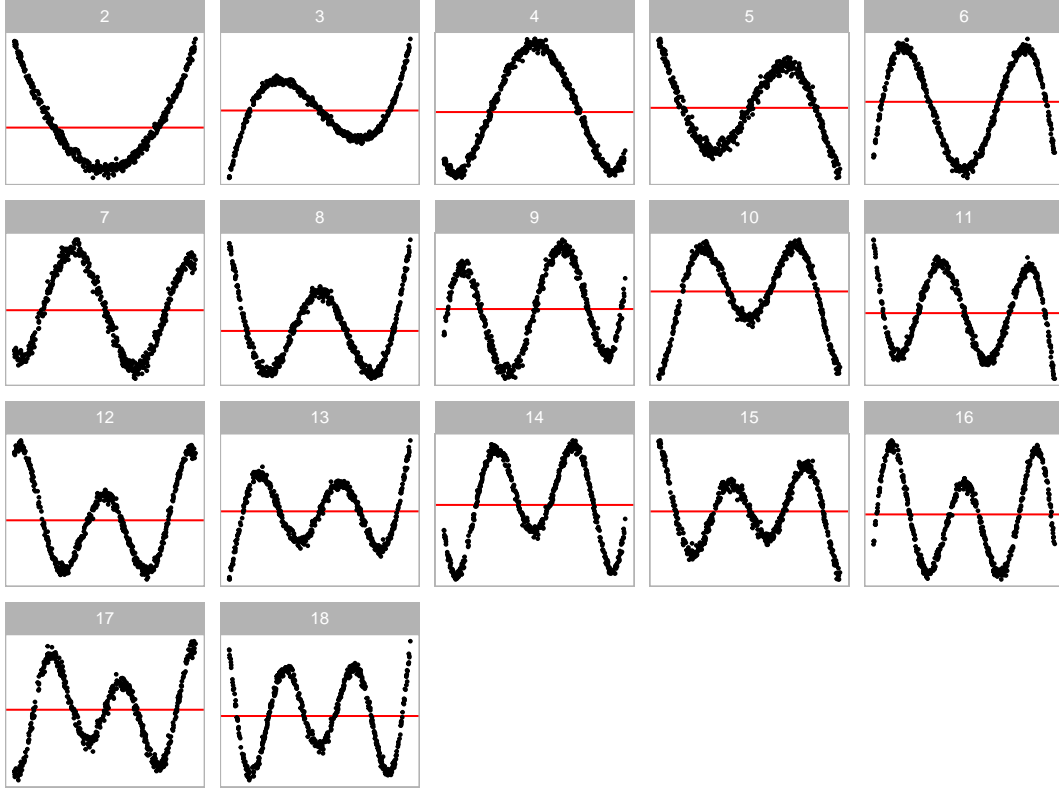

Figure A1. Non-linearity forms generated for the synthetic data simulation. The 17 shapes are generated by varying the order of polynomial given by j in $He_j(\cdot)$.

Additionally, scaling factor \mathbf{k} directly affects the error distribution and it is correlated with \mathbf{x}_1 and \mathbf{x}_2 . If $b \neq 0$ and $\varepsilon \sim N(\mathbf{0}_n, \sigma^2 \mathbf{I}_n)$, the constant variance assumption will be violated. Parameter a is a shape parameter controlling the location of the smallest variance in a residual plot as shown in Figure A2.

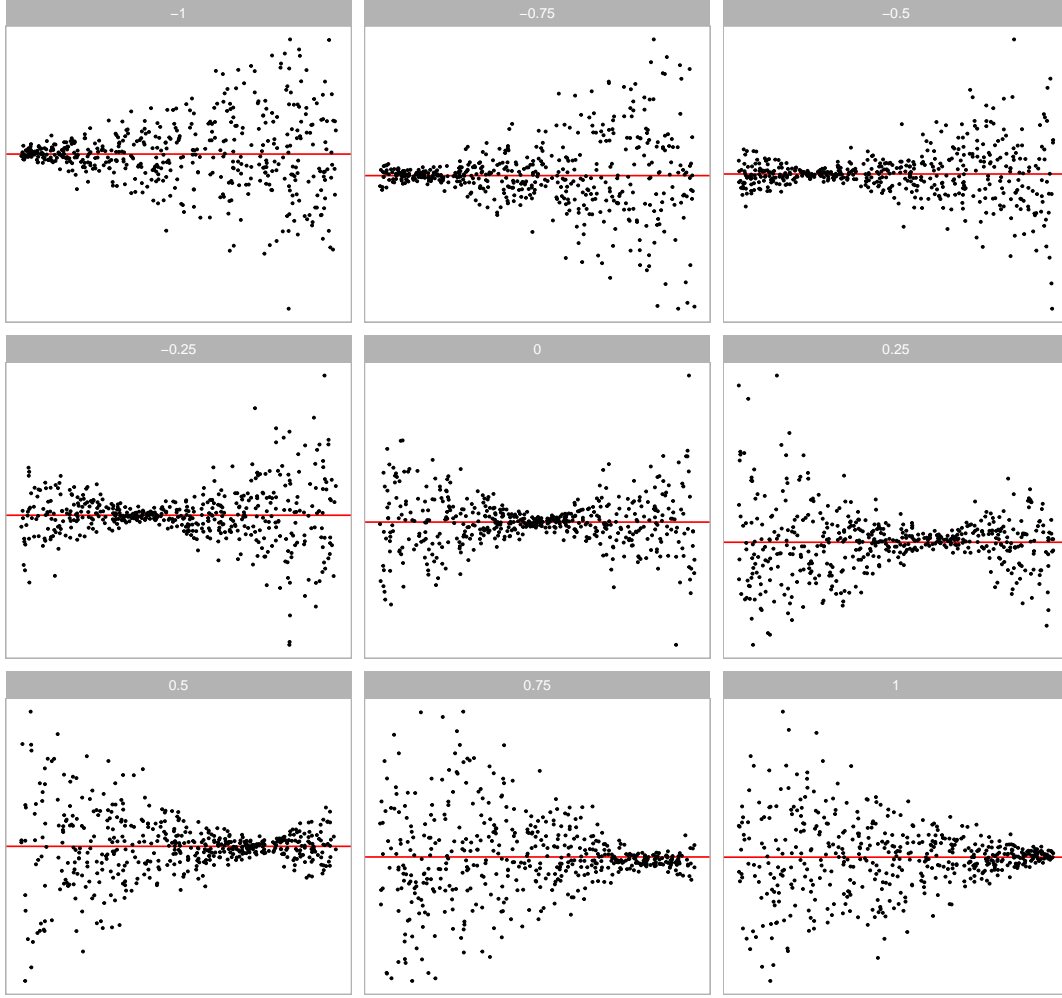

Figure A2. Heteroskedasticity forms generated for the synthetic data simulation. Different shapes are controlled by the continuous factor a between -1 and 1. For $a = -1$, the residual plot exhibits a "left-triangle" shape. And for $a = 1$, the residual plot exhibits a "right-triangle" shape.

Non-normality violations arise from specifying a non-normal distribution for ε . In the synthetic data simulation, four distinct error distributions are considered, including discrete, uniform, normal, and lognormal distributions, as presented in Figure A3. Each distribution imparts unique characteristics in the residual plot. The discrete error distribution introduces discrete clusters in residuals, while the lognormal distribution typically yields outliers. Uniform error distribution may result in residuals filling the entire space of the residual plot. All of these distributions exhibit visual distinctions from the normal error distribution.

Equation A1 accommodates the incorporation of the second predictor \mathbf{x}_2 . Introducing it into the data generation process by setting $\beta_1 = 1$ significantly enhances the

Figure A3. Non-normality forms generated for the synthetic data simulation. Four different error distributions including discrete, lognormal, normal and uniform are considered.

complexity of the shapes, as illustrated in Figure A4. In comparison to Figure A1, Figure A4 demonstrates that the non-linear shape resembles a surface rather than a single curve. This augmentation can facilitate the computer vision model in learning visual patterns from residual plots of the multiple linear regression model.

In real-world analysis, it is not uncommon to encounter instances where multiple model violations coexist. In such cases, the residual plots often exhibit a mixed pattern of visual anomalies corresponding to different types of model violations. Figure A5 and Figure A6 show the visual patterns of models with multiple model violations.

The predictors, \mathbf{x}_1 and \mathbf{x}_2 , are randomly generated from four distinct distributions, including $U(-1, 1)$ (uniform), $N(0, 0.3^2)$ (normal), $\text{lognormal}(0, 0.6^2)/3$ (skewed) and $U\{-1, 1\}$ (discrete uniform).

Figure A4. Residual plots of multiple linear regression models with non-linearity issues. The 17 shapes are generated by varying the order of polynomial given by j in $He_j(\cdot)$. A second predictor \mathbf{x}_2 is introduced to the regression model to create complex shapes.

A.2. *Balanced Dataset*

To train a robust computer vision model, we deliberately controlled the distribution of the target variable D in the training data. We ensured that it followed a uniform distribution between 0 and 7. This was achieved by organizing 50 buckets, each exclusively accepting training samples with D falling within the range $[7(i-1)/49, 7i/49)$ for $i < 50$, where i represents the index of the i -th bucket. For the 50-th bucket, any training samples with $D \geq 7$ were accepted.

With 80,000 training images prepared, each bucket accommodated a maximum of $80000/50 = 1600$ training samples. The simulator iteratively sampled parameter values from the parameter space, generated residuals and fitted values using the data generation process, computed the distance, and checked if the sample fitted within the corresponding bucket. This process continued until all buckets were filled.

Similarly, we adopted the same methodology to prepare 8,000 test images for per-

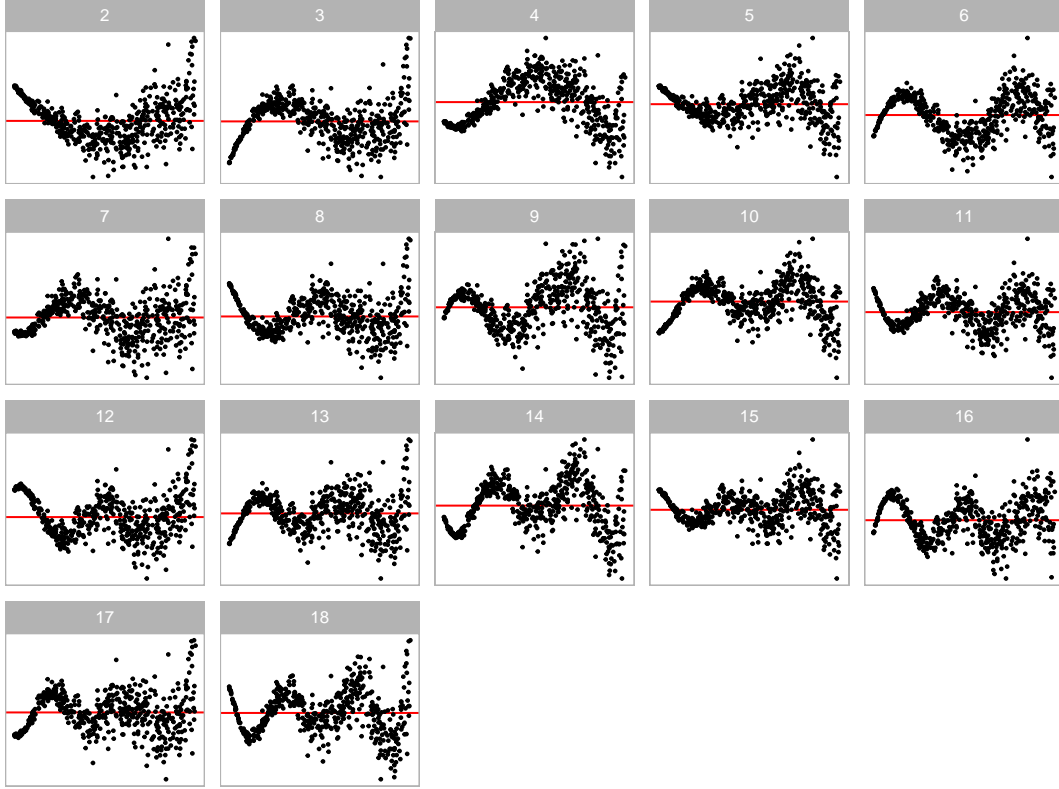

Figure A5. Residual plots of models violating both the non-linearity and the heteroskedasticity assumptions. The 17 shapes are generated by varying the order of polynomial given by j in $He_j(\cdot)$, and the "left-triangle" shape is introduced by setting $a = -1$.

formance evaluation and model diagnostics.

Appendix B. Model Training

To achieve a near-optimal deep learning model, hyperparameters like the learning rate often need to be fine-tuned using a tuner. In our study, we utilized the Bayesian optimization tuner from the `KerasTuner` Python library (O'Malley et al. 2019) for this purpose. A comprehensive list of hyperparameters is provided in Table B1.

The number of base filters determines the number of filters for the first 2D convolutional layer. In the VGG16 architecture, the number of filters for the 2D convolutional layer in a block is typically twice the number in the previous block, except for the last block, which maintains the same number of convolution filters as the previous one. This hyperparameter aids in controlling the complexity of the computer vision model. A higher number of base filters results in more trainable parameters. Likewise, the

Figure A6. Residual plots of models violating both the non-normality and the heteroskedasticity assumptions. The four shapes are generated by using four different error distributions including discrete, lognormal, normal and uniform, and the "left-triangle" shape is introduced by setting $a = -1$.

number of units for the fully-connected layer determines the complexity of the final prediction block. Increasing the number of units enhances model complexity, resulting in more trainable parameters.

The dropout rate and batch normalization are flexible hyperparameters that work in conjunction with other parameters to facilitate smooth training. A higher dropout rate is necessary when the model tends to overfit the training dataset by learning too much noise (Srivastava et al. 2014). Conversely, a lower dropout rate is preferred when the model is complex and challenging to converge. Batch normalization, on the other hand, addresses the internal covariate shift problem arising from the randomness in weight initialization and input data (Goodfellow, Bengio, and Courville 2016). It helps stabilize and accelerate the training process by normalizing the activations of each layer.

Additionally, incorporating additional inputs such as scagnostics and the number of observations can potentially enhance prediction accuracy. Therefore, we allow the

Table B1. Name of hyperparameters and their corresponding domain for the computer vision model.

| Hyperparameter | Domain |
|---|-----------------------------|
| Number of base filters | {4, 8, 16, 32, 64} |
| Dropout rate for convolutional blocks | [0.1, 0.6] |
| Batch normalization for convolutional blocks | {false, true} |
| Type of global pooling | {max, average} |
| Ignore additional inputs | {false, true} |
| Number of units for the fully-connected layer | {128, 256, 512, 1024, 2048} |
| Batch normalization for the fully-connected layer | {false, true} |
| Dropout rate for the fully-connected layer | [0.1, 0.6] |
| Learning rate | $[10^{-8}, 10^{-1}]$ |

tuner to determine whether these inputs were necessary for optimal model performance.

The learning rate is a crucial hyperparameter, as it dictates the step size of the optimization algorithm. A high learning rate can help the model avoid local minima but risks overshooting and missing the global minimum. Conversely, a low learning rate smoothens the training process but makes the convergence time longer and increases the likelihood of getting trapped in local minima.

Our model was trained on the MASSIVE M3 high-performance computing platform (Goscinski et al. 2014), using TensorFlow (Abadi et al. 2016) and Keras (Chollet et al. 2015). During training, 80% of the training data was utilized for actual training, while the remaining 20% was used as validation data. The Bayesian optimization tuner conducted 100 trials to identify the best hyperparameter values based on validation root mean square error. The tuner then restored the best epoch of the best model from the trials. Additionally, we applied early stopping, terminating the training process if the validation root mean square error fails to improve for 50 epochs. The maximum allowed epochs was set at 2,000, although no models reached this threshold.

Based on the tuning process described above, the optimized hyperparameter values are presented in Table B2. It was observable that a minimum of 32 base filters was necessary, with the preferable choice being 64 base filters for both the 64×64 and 128×128 models, mirroring the original VGG16 architecture. The optimized dropout rate for convolutional blocks hovered around 0.4, and incorporating batch normalization

Table B2. Hyperparameters values for the optimized computer vision models with different input sizes.

| Hyperparameter | 32×32 | 64×64 | 128×128 |
|---|----------------|----------------|------------------|
| Number of base filters | 32 | 64 | 64 |
| Dropout rate for convolutional blocks | 0.4 | 0.3 | 0.4 |
| Batch normalization for convolutional blocks | true | true | true |
| Type of global pooling | max | average | average |
| Ignore additional inputs | false | false | false |
| Number of units for the fully-connected layer | 256 | 256 | 256 |
| Batch normalization for the fully-connected layer | false | true | true |
| Dropout rate for the fully-connected layer | 0.2 | 0.4 | 0.1 |
| Learning rate | 0.0003 | 0.0006 | 0.0052 |

for convolutional blocks proved beneficial for performance.

All optimized models chose to retain the additional inputs, contributing to the reduction of validation error. The number of units required for the fully-connected layer was 256, a relatively modest number compared to the VGG16 classifier, suggesting that the problem at hand was less complex. The optimized learning rates were higher for models with higher resolution input, likely because models with more parameters are more prone to getting stuck in local minima, requiring a higher learning rate.

Appendix C. Model Violations Index

In Section 5.1, we noted that a pre-computed lattice of \hat{D} quantiles can reduce the computation cost of lineup tests. Another practical approach is to assess model performance directly using the value of \hat{D} .

The estimator \hat{D} captures the difference between the true and reference residual distributions, which reflects the extent of model violations, making it instrumental in forming a model violations index (MVI). However, when more observations are used in regression, the value of \hat{D} tends to increase logarithmically. This is because $D = \log(1 + D_{KL})$, and under the assumption of independence, D_{KL} is the sum of $D_{KL}^{(i)}$ across all observations. This does not mean that \hat{D} becomes less reliable. In fact, larger samples often make model violations more visible in residual plots, unless strong overlapping masks the patterns.

Table C1. Degree of model violations or the strength of the visual signals according to the Model Violations Index (MVI). The constant C is set to be 10.

| Degree of model violations | Range ($C = 10$) |
|----------------------------|----------------------|
| Strong | $\text{MVI} > 8$ |
| Moderate | $6 < \text{MVI} < 8$ |
| Weak | $\text{MVI} < 6$ |

However, to create a standardized and generalizable index, it is important to adjust for the effect of sample size. Therefore, the Model Violations Index (MVI) is proposed as

$$\text{MVI} = C + \hat{D} - \log(n), \quad (\text{C1})$$

where C is a sufficiently large constant to ensure the result remains positive, and the $\log(n)$ term offset the increase in D with larger sample sizes.

Figure C1 displays the residual plots for fitted models exhibiting varying degrees of non-linearity and heteroskedasticity. Each residual plot's MVI is computed using Equation C1 with $C = 10$. When $\text{MVI} > 8$, the visual patterns are notably strong and easily discernible by humans. In the range $6 < \text{MVI} < 8$, the visibility of the visual pattern diminishes as MVI decreases. Conversely, when $\text{MVI} < 6$, the visual pattern tends to become relatively faint and challenging to observe. Table C1 provides a summary of the MVI usage and it is applicable to other linear regression models.

Figure C1. Residual plots generated from fitted models exhibiting varying degrees of (A) non-linearity and (B) heteroskedasticity violations. The model violations index (MVI) is displayed atop each residual plot. The non-linearity patterns are relatively strong for $MVI > 8$, and relatively weak for $MVI < 6$, while the heteroskedasticity patterns are relatively strong for $MVI > 8$, and relatively weak for $MVI < 6$.
